

# Sponsorships In Livestreaming: Monetization And Disclosure Behavior Of Influencers On Twitch

Ivan Li\*

June 6, 2023

[Click for Most Recent Version](#)

## Abstract

Influencer marketing has elements of both pay-for-placement and traditional advertising. Practitioners argue that it is more similar to placement, while regulators believe that it operates more like advertising. Whether influencer marketing is placement or advertising matters given increased regulatory attention in this industry. I study why influencers disclose and the impacts of disclosure regulation on Twitch.tv, the largest online video game livestreaming platform. I motivate a dynamic model of influencer sponsored content choice from a lightly modified Spence (1978) signaling model. I demonstrate that pooling equilibria are consistent with placement mechanisms, while separating equilibria occur because of advertising mechanisms. My descriptive evidence supports predictions generated from a separating equilibrium where influencers disclose “high” type sponsors and pool “low” type sponsors with organic content, suggesting that influencer marketing behaves more like advertising. Counterfactual estimates support my claim; a policy enforcing strict disclosure would lead to a 16.5% decrease in sponsored content streams and a 0.67% increase in platform viewership. Influencers substitute away from low-type sponsorships, suggesting that disclosure may improve consumers’ platform experience in contrast to practitioners’ efficiency rationale.

**Keywords:** Influencer marketing, Online livestreaming, Advertisement disclosure, Product placement, Brand alignment, Dynamic discrete choice

\*Li: Stanford GSB, 655 Knight Way, Stanford CA 94305. Email: yilunli@stanford.edu. Working paper. I am extremely grateful to my advisor Wesley Hartmann for awesome guidance. I thank Lanier Benkard, Ryan Dew, Sam Goldberg, Yewon Kim, Navdeep Sahni, Ali Yurukoglu, and seminar participants at Stanford GSB for helpful comments. Researcher(s)’ own analyses calculated (or derived) based in part on data from Twitch.tv’s public API. The conclusions drawn from the Twitch API data are those of the researcher and do not reflect the views of Twitch or Amazon. All errors are my own.

# 1 Introduction

Consumers frequently encounter situations where products are placed in front of them. In grocery stores, shelves are carefully organized to cater to consumer needs. Characters in shows or movies may drive particular cars. Social media platforms are flooded with product endorsements by celebrities and influencers. Some placements reflect the organic preferences of the store or celebrity, while others involve financial transactions that consumers may not be aware of. Coase (1979) argues that disclosing such payments can be disruptive, as is the case with product placements in shows and movies. In other contexts, disclosure is legally required but can be done so to varying degrees of subtlety to limit disruption. However, if disclosure can be highly diminished in some contexts, why then would prominent disclosure ever occur?

This paper studies why voluntary, prominent disclosure occurs. The ability to choose disclosure levels for pay-for-placement attempts enables the brand or partner to shift the advertising mechanisms that signal quality or match values and thereby separate this placement opportunity from other less valuable or relevant alternatives. I choose to study disclosure in the empirical setting of influencer marketing - in particular, online video game livestreaming - where disclosure policies have been enacted for the sake of preventing consumer deception and upholding the principles of truth-in-advertising. Platforms' implementation has been lenient, leaving influencers with much flexibility in determining intensity of disclosure. Understanding influencers' behavior regarding disclosure is a key step towards realizing the implications of marketing disclosure regulation.

Regulation has faced pushback from practitioners in the “creator economy” who argue that influencer marketing is no different from product placement on TV and movies.<sup>1</sup> The FTC corroborates the opinion that product placement does not need to be disclosed:

The FTC has expressed the opinion that under the FTC Act, product placement (merely showing products or brands in third-party entertainment content – as distinguished from sponsored content or disguised commercials) doesn't require a disclosure that the advertiser paid for the placement.<sup>2</sup>

The fundamental tension in my setting is determining whether or not influencer marketing is pay-for-placement or advertising. In the digital economy, practitioners and scholars alike consider advertising and pay-for-placement interchangeable. A significant portion of paid placement takes place in contexts involving active consumer searches on search engines like Google, review platforms such as Yelp, or online retailers like Amazon. Pay-for-placement in such settings becomes advertising because the goal of the payment is to both secure a better location and attract attention to the advertising brand. While social media platforms like Instagram, YouTube, and TikTok also facilitate search, some underlying mechanisms behind pay-for-placement in influencer marketing are different. Payments to the influencer do not directly secure better positioning in the search

---

<sup>1</sup>See <https://seedatl.com/ftcs-social-media-product-placement-rules-vs-tv-movie-product-placements/> and <https://sabguthrie.info/product-placement-double-standards/> for examples

<sup>2</sup><https://www.ftc.gov/business-guidance/resources/ftcs-endorsement-guides-what-people-are-asking>

algorithm; in many instances these payments instead lead to worse search rankings due to worse performance. Additionally, a brand’s primary motive for payment may not be to attract attention. Rather, the brand may want to use influencer marketing to demonstrate the use and quality of their products or services in a manner that seems organic, not sponsored. Consumers end up searching through relevant content that may be organic or sponsored and disclosure of payments is highly variable.

Failing to distinguish between pay-for-placement and advertising could lead to inadequate policy recommendations. If influencer marketing is considered pay-for-placement, then policymakers should refrain from strict disclosure regulation. The inefficiency of payola legislation in the 1950s and 60s, as argued by Coase (1979), highlights the alignment of incentives among DJs, radio stations, and consumers in undisclosed pay-for-play arrangements. On the other hand, if influencer marketing is considered promotion, then enforcing disclosure may be efficient due to various advertising mechanisms such as signaling (Sahni and Nair, 2020a) or celebrity effects (Chung et al., 2013; Knittel and Stango, 2014).

I introduce a simple, stylized example based off of Spence (1978)’s signaling model to highlight the differences between pay-for-placement and advertising. There are two players in the game: influencers and followers. The influencer realizes varying qualities of advertising brands and chooses a disclosure decision. Influencers receive payoffs from followers and incur reputational costs for disclosing sponsorship. Followers receive payoffs depending on the quality of the brand. When costs of disclosure are high across all brand types, a pooling equilibrium exists where no disclosure exists. Pooling equilibria are more likely to exist in placement scenarios like radio, TV shows, and movies, where disclosing the placement would be highly disruptive Coase (1979). When costs of disclosure are lower for better types, a separating equilibrium exists where these high types disclose and low types do not. Advertising situations are more likely to exhibit this equilibrium because the high types benefit from leveraging advertising mechanisms to distinguish themselves from low types without it being prohibitively costly.

The stylized example generates some testable predictions for the influencer marketing setting. Because disclosure voluntarily exists, influencer marketing likely resides in the separating equilibrium scenario. For a separating equilibrium, the example first predicts that engagement for high disclosure content should be higher than low disclosure. Second, costs of disclosure should be elevated for low types compared to high types. Third, when a low type discloses, off-path beliefs should drive engagement up temporarily.

To test these predictions, I use a dataset comprising more than 1,000 English-speaking influencers (“streamers”), from Twitch.tv, the world’s largest online video game livestreaming platform. On Twitch, streamers engage in live broadcasts of their gameplay, entertaining viewers with their gaming experiences, reactions, and interactive chat. I focus on sponsorships received by streamers from video game developers who offer a lump sum payment in exchange for showcasing their games during the streams. While it is not feasible to directly observe fully obfuscated sponsors in this context, streamers have the ability to control the level of disclosure for their sponsored content. As-

suming that all sponsored content is disclosed, I use the variation in disclosure intensity as a means to measure the effects of disclosure.<sup>3</sup> Even in absence of enforcement, about 13% of sponsored observations are prominently disclosed.

All three testable predictions hold true in my data. OLS regressions results show that high disclosure streams are correlated with 6-13% higher viewership compared to low disclosure streams, commanding viewership on par with organic streams. Under a reasonable assumption and an IV regression strategy, I show that reputational costs for high disclosure are higher among low types than high types. Using follower change during a stream as a proxy for reputation change, influencers selecting into high disclosure incur an inverse-hyperbolic-sin (IHS) cost between 0.47 and 0.69. The IV regression pins the lower bound of the population high disclosure cost at 1.48. Hence, the subset of influencers selecting into high disclosure are promoting sponsors with lower disclosure costs, and these sponsors should be high types. The IV regression also predicts an unbiased, positive effect on viewership for high disclosure streams, consistent with off-equilibrium path outcomes from the stylized example.

Finally, I construct a measure of “alignment” to provide more evidence that selection this a separating equilibrium occurs for high types. This is a correlational measure between the qualitative characteristics of video games and a streamer’s historical frequencies of playing games with these characteristics. For the subset of streamers in the lower quartile of the number of unique games played, they choose to disclose games that are more highly aligned. The profile of high disclosure sponsored games looks very similar to the profile of organically chosen games. The games that a not prominently disclosed are much lower in alignment and look much different than a typical organically chosen game. This finding further supports the separating equilibrium prediction where streamers disclose games with better types. From these descriptive findings I refute practitioners’ claims that influencer marketing is placement. Influencer marketing behaves more akin to advertising because some mechanisms of advertising such as attention matter to influencers.

Given this conclusion, I attempt to quantify the effects of a strict disclosure policy, expecting to find positive effects especially for followers. I build on the stylized example, extending the model into a dynamic structural model of influencer content decisions. In each period, influencers have the option to create sponsored or organic content. If they choose sponsored content, they must also simultaneously make a high/low disclosure decision. Estimated parameters suggest that choosing sponsored content hurts influencer payoffs in the short term through lower concurrent viewership relative to choosing organic content. It also lowers the number of followers acquired, affecting influencers in future periods since followers help determine viewership.

I allow for selection into high disclosure by introducing an exogenous, unobserved state variable akin to brand “alignment” or “type.” This state alters the payoff of high disclosure; in the high state, prominent disclosure will be more lucrative than low disclosure. I assume influencers observe this state before making their decisions, thereby allowing selection into high disclosure when it is

---

<sup>3</sup>The FTC cares about the intensive margin - they want the disclosure to be “hard to miss”. [https://www.ftc.gov/system/files/documents/plain-language/1001a-influencer-guide-508\\_1.pdf](https://www.ftc.gov/system/files/documents/plain-language/1001a-influencer-guide-508_1.pdf)

advantageous to do so. Followers respond to influencers’ disclosure choices and the alignment of the brand.

I estimate the model using the expectation-maximization algorithm from Arcidiacono and Miller (2011), which addresses persistent unobserved heterogeneity. My unobserved “alignment” state acts as a transient, one-period unobserved state which simplifies the estimation algorithm. I am able to identify this unobserved state using correlation between multiple outcomes affected by disclosure. As an example, suppose that synergies exist between high disclosure and high alignment. Then, observing a relatively large number of viewers plus observing many followers acquired during a high disclosure sponsored stream would place a large probability on being in the high state.

Model estimates suggest that disclosing a poorly aligned sponsor draws attention to the sellout nature of the content, decreasing viewership and negatively impacting the number of followers of the influencer. Conversely, prominently disclosing a well-aligned sponsor increases viewership beyond levels of organic content. These results are in line with the predictions from the stylized example.

In my headline counterfactual, the frequency of sponsored content decreases by 16.5% when prominent disclosure is enforced. This decline is driven by influencers’ strategic behavior; in states where the sponsor is poorly aligned (98.9% occurrence), sponsorship frequency decreases by 18%, whereas this decrease is just 1% in the well-aligned state (1.1% occurrence). Thus, almost all of the counterfactual policy’s impact comes from the rejection of poorly aligned sponsors that influencers would have otherwise accepted in the absence of regulation. If poorly aligned sponsors imply low quality streams, then consumers are better off in the counterfactual scenario. Overall viewership on the platform increases by 0.67% as influencers substitute away from low type sponsors into organic content rather than no stream. Therefore, the platform also benefits from the policy.

My main contribution is showing that influencers will produce less sponsored content when prominent disclosure is enforced. This result is achieved by building off of three other contributions. First, I argue that pay-for-placement and advertising are separate marketing practices in the digital economy. I highlight equilibrium objects in a signaling model that coincide with mechanisms distinguishing advertising from placement. Discussion of placement versus advertising has occurred in more traditional marketing settings like slotting fees (Sullivan, 1997; Sudhir and Rao, 2006; Hristakeva, 2022). Second, I find a unique setting where voluntary disclosure exists and suggest a mechanism for why it occurs. I use my framework to confirm that influencer marketing in the livestreaming setting is indeed advertising. Third, I document the dynamic short and long-term incentives that influencers face and quantify them using a structural model.

The two papers closest to mine are Ershov and Mitchell (2020) and Cheng and Zhang (2022). The former studies the effects of advertisement disclosure on influencer content creation using a policy change in Germany, while the latter looks at reputation burning effects for YouTube creators. My paper more carefully considers mechanisms behind sponsorship and disclosure. With regard to Ershov and Mitchell (2020), I demonstrate that the placement versus advertising margin and avenues for selective disclosure are necessary to quantify effects of disclosure policy. While Cheng and Zhang (2022) consider reputation burning and brand-influencer fit, I show that disclosure is a

crucial lever used by influencers to signal good fit and mitigate reputational costs.

I also contribute to the burgeoning literature on influencer marketing. Much of this literature is theoretical, especially regarding disclosure (Berman and Zheng, 2020; Fainmesser and Galeotti, 2021; Mitchell, 2021; Pei and Mayzlin, 2022), and tends to focus on consumer welfare. Instead, I focus on the supply side of the market to understand why influencers may decide to advertise and disclose in lieu of creating organic content. I also measure consumer demand for sponsored content, which may provide the advertising brand some insight into the effectiveness of influencer marketing campaigns (Rajaram and Manchanda, 2020; Morozov and Huang, 2021; Li et al., 2021; Yang et al., 2021). I define and quantify “brand alignment” between a brand and an influencer using historical revealed preferences, providing future researchers a method to quantitatively analyze hypotheses regarding influencer credibility, authenticity, and influencer-product congruence (Schouten et al., 2020; Kim and Kim, 2021; Pöyry et al., 2021). My long panel of influencer choices allows me to identify selection mechanisms incentivizing voluntary disclosure that lab experiments are unable to consider (Boerman, 2020; Kay et al., 2020).

Moreover, I contribute to the literature on native advertising and its disclosure (Evans et al., 2019; Aribarg and Schwartz, 2020; Sahni and Nair, 2020b). One paper to note is Sahni and Nair (2020a), who use a field experiment to study effects of disclosing search ads on a Yelp-like restaurant platform. They find that disclosure increases clickthrough and calls to advertising restaurants. They attribute this to a “signaling effect,” whereby customers perceive advertising restaurants to be higher in quality than non-advertising ones. My findings are consistent in that disclosure seems to serve as a signal in some circumstances. However, I find that disclosure can be detrimental in circumstances where the sponsor is not well aligned. This phenomenon goes away in the search setting, perhaps due to quality scores in search auctions acting as “alignment,” minimizing the possibility that a poorly aligned ad is shown to the consumer. Another explanation could be that pay-for-placement in search always acts as advertising so signaling mechanisms are predominant, whereas “low alignment” influencer marketing settings might not necessarily be advertising.

Finally, my paper is one of the few that uses the online livestreaming setting. There is some focus on non-sponsorship mechanisms of influencer monetization such as donations and various pay-what-you-want mechanisms (Lin et al., 2021; Lu et al., 2021). Morozov and Huang (2021) study the effects of streaming on video game usage more generally, treating all video game streaming as advertising. Simonov et al. (2021) uses a specific subset of Twitch data from streams of Counter-Strike:Go tournaments in addition to viewer-level chat data to study the role of suspense. I add to this literature by focusing on the characterization of sponsored content as placement or advertising and its production/obfuscation.

## 2 Institutional Detail and Data

### 2.1 The Online Livestreaming Industry

The online livestreaming economy has been booming in recent years. Audiences watched almost 100 million hours of online livestreams per day in Q1 2021<sup>4</sup>. The most popular livestreamers command tens if not hundreds of thousands of concurrent viewers and sign exclusive streaming contracts worth tens of millions of dollars<sup>5</sup>. Twitch, specifically, occupies about 70% market share. On average, there are 2.5 million concurrent viewers on Twitch.tv and 90,000 unique live streamers at any moment. Influencers on the Twitch platform usually stream themselves playing video games or “just chatting,” which is a general category for “in real life (IRL)” streams.

Advertisers have taken note of streamers’ impact; sponsored livestream occurrences increased 88% year over year (YoY) and watch time increased 137% YoY in Q1 2021. Sponsored livestreams occupied 3% of total watch time as of March 2021.

Streamers have three broad ways to monetize. The first way involves Twitch-embedded ads, which are pre-negotiated by Twitch and its advertisers. Similar to Youtube ads, these ads usually run when a consumer first lands on a streamer’s livestream. Streamers can also press an “ad button” whenever they want to run such ads. There is no way to obfuscate these ads, payment depends upon the calculated reach of the ads, and in recent years, these ads have become unblockable and unskippable. The second way involves direct contributions from viewers. Viewers can unlock a streamer’s premium channel features by becoming a paid “subscriber,” which costs anywhere from \$5 to \$25 a month. Streamers then receive a portion of the subscription revenue. Streamers can also receive donations from viewers through Twitch or a third party.<sup>6</sup>

External sponsorships are the third way, but even then there are nuances. I define two subcategories of sponsorships - brand deals and game developer deals. A brand deal generally involves any product that is not a video game itself. Apparel, computer hardware, and food delivery services are examples of brand deals. These sponsorships are not the focus in this setting because they generally do not alter the content of the stream. Game developer (game dev) deals are product demonstrations or game playthroughs that alter the content of a stream. The typical game developer deal involves a streamer playing a sponsored game for a few hours.

Sponsorships require negotiation around compensation and deliverables. Disclosure, according to industry insiders, is rarely part of the negotiation. Some sponsors may have certain preferences over disclosure practices,<sup>7</sup> but sponsors usually do not dictate how influencers should disclose.

---

<sup>4</sup>Stream Hatchet Live Game Streaming Trends Q1 2021

<sup>5</sup>Anecdotal evidence from streamers within the industry, see: <https://www.youtube.com/watch?v=qDMJQeHxYeQ>

<sup>6</sup>Livestream donations are the object of focus in Lin et al. (2021) and Lu et al. (2021)

<sup>7</sup>For example, in my data, the game *Legends of Runeterra* almost always has #ad at the beginning of the stream title across different influencers

## 2.2 Data

My data comes from two main sources. Streaming data is collected from Twitch.tv’s API. I collect data on the top 430 english speaking Twitch streamers starting in February 2021. In August 2021, I expanded the data collection to the top 1,300 english speaking Twitch streamers. In this version of the paper, the data collection period ends on April 30, 2023.

Every 5 minutes, I am able to obtain, for each streamer, the live/offline status of their stream, the number of concurrent viewers (if live), the number of total views a channel has, the title of the stream, the game being played, and the number of users following the channel.

Certain metrics are not updated every five minutes, so I aggregate data up to the user-stream-game level. I drop stream-game combinations that are live for less than 30 minutes. For example, if a user is live for 6 hours on Sunday, October 17th and they spend their first 2 hours streaming League of Legends, the next 1 hour 45 minutes streaming Grand Theft Auto V, the next 15 minutes “Just Chatting”, and finally spend their last 2 hours going back to League of Legends, this one stream session would be broken up into three observations in my data even though there are four stream-game combinations. For the structural model, data is aggregated one level further, up to the daily level.

Statistic (per streamer)	Mean	St. Dev.	Min	Pctl(25)	Median	Pctl(75)	Max
Observations	578.64	433.25	8	328.5	522	745.5	7,890
Num. streams	384.06	197.89	6	248.5	391	511.5	1,841
Num. unique games	51.65	77.75	1	12	26	61	1,148
Obs any sponsor	25.49	59.02	0	1	9	28	1,110

Obs game dev	10.36	21.35	0	0	3	12	355
Obs game dev hi disc	1.38	4.75	0	0	0	1	74
Avg. conc. viewership	3,768.32	8,978.60	94.80	739.33	1,458.85	3,038.82	106,316.80
Avg. stream+game length (hr)	4.82	2.26	1.28	3.21	4.51	5.91	23.38
Game dev sponsor	0.017	0.031	0.000	0.000	0.007	0.021	0.382
Any sponsor	0.040	0.067	0.000	0.002	0.018	0.049	0.848
Game dev hi disc (conditional on ad)	0.142	0.242	0.000	0.000	0.000	0.203	1.000
Any sponsor hi disc (conditional on ad)	0.111	0.207	0.000	0.000	0.000	0.125	1.000
Current followers	621,570	1,137,079	5,934	135,228	286,897	639,870	17,807,142
Initial followers	463,232	950,210	1,571	99,755	200,392	458,688	16,714,288
Follower change	158,338	328,822	-53,903	14,155	44,880	152,886	3,786,212

Table 1: Streamer summary statistics, 1159 streamers

After selecting streamers based on some criteria (see Section 2.4 for more detail), I am left with 1,159 streamers and around around 670,000 observations at the user-stream-game level. Streamer-level summary statistics are provided in Table 1. Over two-thirds (821) of all streamers have done a game dev sponsored stream. Out of these 821 influencers, 377 have highly disclosed a sponsored stream at least once. The median streamer has 551 stream-game observations over 394 streams, about 1.4 separate game sessions per stream. The median streamer has 4 observations with a game dev sponsor, comprising about 1% of their observations.

The median streamer commands just under 1,500 average concurrent viewers (ACV) during

a stream.<sup>8</sup> ACV is defined as the mean number of unique viewers on a stream at any point the streamer is live. This is a crucial metric, as ACV is how Twitch culture tends to measure the size of a streamer.<sup>9</sup>

Sponsored content streams occur rather infrequently; about 12,000 or 1.8% of all observations are sponsored. About 1,600 of these are considered “prominently disclosed” under my definition (see Section 2.3).

Game characteristics are collected from the Internet Game Database (IGDB) API, which is a website owned and operated by Twitch. For each game, I can access characteristics such as its genres, themes, storylines, release date, user and critic ratings, and much more. Twitch uses IGDB on its own website to make it easier for viewers to search for games. In my data sample, streamers play almost 9,000 unique video games.

## 2.3 Identifying Sponsored Streams

One implicit assumption I make is that streamers truthfully disclose all sponsored content. There is good reason to believe that disclosure happens; FTC regulations require disclosure of any “material connections” between an influencer and a brand<sup>10</sup>, and so does Twitch’s terms of service<sup>11</sup>. Streamers in my data are among the most popular on Twitch, many of whom treat streaming as a full-time job. The threat of enforcement from the FTC and Twitch to their livelihoods should be enough to ensure disclosure<sup>12</sup>. The ability to obfuscate while complying should also limit non-disclosure. Discussions with talent management agencies in this industry support this claim that streamers generally are well-behaved with respect to disclosing sponsored content.

When viewers browse for a stream, they can see a thumbnail picture of the livestream, as well as information such as the title of the stream, the name of the streamer, and the game being played currently by the streamer. Figure 1 shows what the viewer observes when browsing for a stream. Prior to clicking on a stream channel and watching the stream, a potential viewer can only find out about the sponsored nature of the stream through the stream title.

I identify sponsored content using a simple string match on the stream titles. Within the stream titles, I search for instances of #ad, #sponsored, and variations of #\*partner (e.g. #EpicPartner). Every stream that simply contains one of these hashtags is tagged as potentially sponsored. To distinguish game dev deals from brand deals, I manually look for each observation if the name of the game being played is contained in the stream title of the sponsored content. Some examples of titles related to brand deals and game dev deals are provided in Table 2. I separately identify high disclosure and low disclosure using the location of the hashtag in the stream title. The length of

---

<sup>8</sup>These are big streamers; for example, <https://twitchtracker.com/day9tv> is a  $\sim 1,500$  viewer streamer who is in the top 0.03% of Twitch

<sup>9</sup>See <https://www.quora.com/Why-do-Twitch-streamers-refer-to-each-other-as-Andy> as an example

<sup>10</sup><https://www.ftc.gov/tips-advice/business-center/guidance/ftcs-endorsement-guides-what-people-are-asking>

<sup>11</sup><https://www.twitch.tv/p/en/legal/terms-of-service/>

<sup>12</sup>Teami Detox Teas is an example of a company recently fined in 2020; celebrities endorsing the product such as Cardi B were warned for their lack of disclosure: <https://www.ftc.gov/news-events/press-releases/2020/03/tea-marketer-misled-consumers-didnt-adequately-disclose-payments>

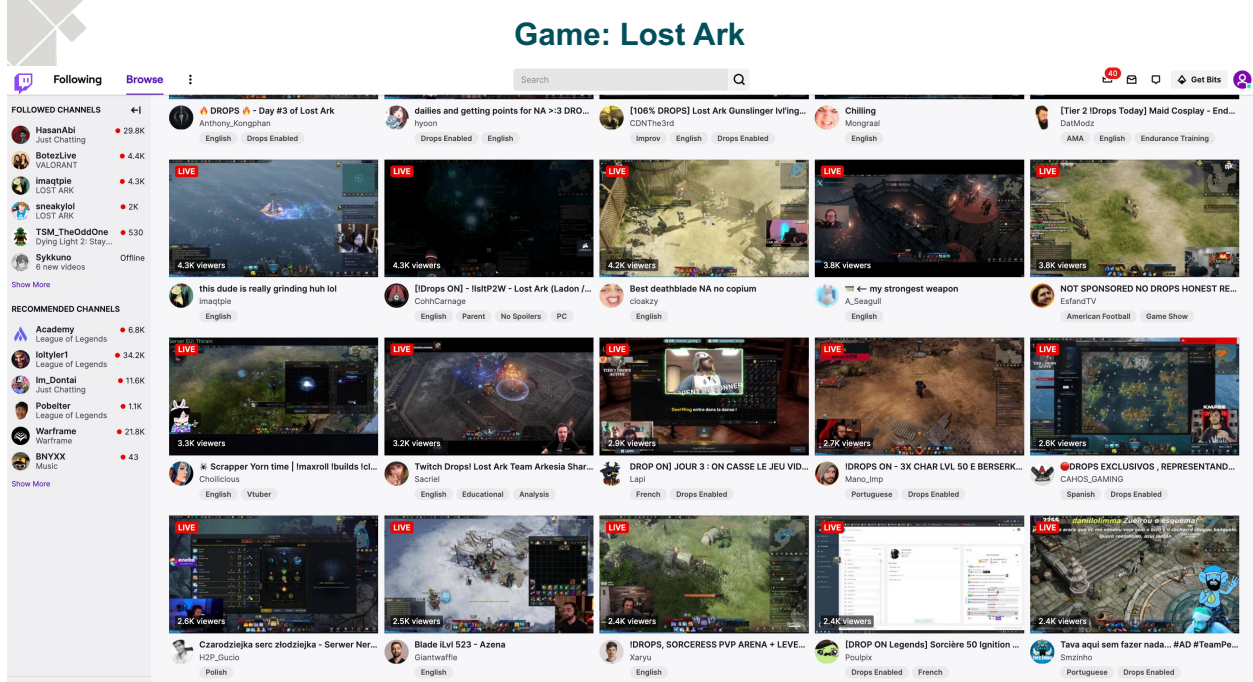

Figure 1: Example of Twitch browse page for game *Lost Ark*

	High Disclosure	Low Disclosure
Game dev	#Sponsored: Legends of Runeterra (Game indicated on stream: Legends of Runeterra)	ROCKET LEAGUE THEN Marvel Strike Force #ad !marvel (Game indicated on stream: MARVEL Strike Force)
Brand	#Sponsored by Universal — Follow @shroud on socials (Game indicated on stream: Apex Legends)	Herman Miller Gaming Giveaway !hmgaming #sponsored (Game indicated on stream: Battlefield 2042)

Table 2: Examples of stream titles

the stream title dynamically adjusts depending on the screen resolution of the viewer’s device. The typical length displayed on the screen is between 20 and 40 characters. Since our counterfactual is to make disclosure quite prominent, I define high disclosure as an indicator function taking on the value 1 if the start of the hashtag is located within 15 characters from the front of the stream title. My results in this paper are robust to alternative definitions of high disclosure, including arbitrary locations greater or less than fifteen characters from the beginning of the stream title. Table 2 gives examples of high and low disclosure ads.

The location of the disclosure label for game dev deals is displayed in Figure 2. The red dashed line indicates the 15th character, where I set my cutoff for high disclosure. There is a mass at zero, indicating that a large number of sponsored streams have the hashtag immediately at the beginning of the stream title. There are no other large masses that jump out, indicating that the decision to put the hashtag at the beginning might be selective.

Figure 2: Absolute location of advertising disclosure, game dev deals only

## 2.4 Data Quality Issues

Since the scraped data comes from a public API, there are some inherent issues. The biggest issues both pertain to the measurement of the number of followers. Twitch struggles in distinguishing real human behavior from bot/automated computer behavior. Botting can be intrusive; bots can inflate the viewership and the number of followers of a channel to make it look more appealing to potential sponsors. Twitch sometimes conducts operations to delete bot accounts and remove bots from follower counts. Botting and bot-hunting can cause inaccurate, lumpy measures of fol-

lowers.<sup>13</sup> I correct for potential “botted” data in the number of followers by identifying periods of bot-following and bot-deleting by Twitch using large jumps and dips, where the follower change is  $\pm 5$  standard deviations from a streamer’s mean follower change, and construct a trend of “true” followers that a streamer has.

Another issue with the data involves channels that are not run by influencers. These channels often include the official channels of video game developers and publishers (e.g. Riot Games), dedicated esports tournament channels (e.g. ESL), and game-specific channels (e.g. Rainbow Six). I remove these Twitch channels because they rarely produced sponsored content and are not an individual brand. Twitch channels that are live for less than 10 days in the timeframe of the data are also removed.

Finally, there are some missing days in the data due to various issues with scraping. A few days are missing because of various server resets that the script was running on. A few days in August 2021 are missing because viewership data was bugged on the API endpoint for those days. A 30 day span from December 2021 - January 2022 is missing because the author went home for winter break and did not check if his scripts were still running. These create the following issues: for descriptive evidence, the biggest loss is sample size. However, over 95% of possible observations ( $\sim 670,000$  observations) remain. For regressions, month-year fixed effects should handle any time-specific systematic biases. If video games streamed during these time periods are not fundamentally different from other time periods, other kinds of descriptive evidence should remain unbiased. For the dynamic model, one may worry about an “initial conditions” kind of problem occurring because of gaps in the data.<sup>14</sup> Biases related to this problem may be mitigated by the long panel; I observe over 700 days of choices for the initial cohort and about 600 days of choices for the additional cohort.<sup>15</sup>

### 3 A Simple, Stylized Model

In this section, I introduce a signaling model that lightly modifies the classic Spence (1978) model. The goal is to find differences between product placement and advertising, explain why we see voluntary disclosure in certain contexts, and generate testable implications for my setting.

There are two players in the model, one “influencer”  $i$  and one “follower”  $f$ . Influencer  $i$  exogenously realizes content with quality  $\theta$ , which is unobserved to follower  $f$ . There are three discrete types  $\theta \in \{\theta_L, \theta_H, \theta_0\}$ , corresponding to low quality ad, high quality ad, and organic content respectively. I place two restrictions on the types,  $\theta_H > \theta_L$  and  $\theta_0 > \theta_L$ , forcing the high and organic types to be strictly better than the low type.

---

<sup>13</sup>As an example: <https://twitchtracker.com/adinross>

<sup>14</sup>e.g. Simonov et al. (2020)

<sup>15</sup>Two additional features of the model directly address this. First, transitions are Markovian, mitigating effects on the transition likelihood. Conditional on observing today’s state, yesterday’s state only matters for computing the likelihood of observing such a transition. I can simply drop observations where I don’t observe the prior day’s state. Second, the model lacks any persistent components (including unobserved heterogeneity), so individual likelihoods do not have to be multiplied over time before taking logs.

The influencer has two actions to choose from,  $j \in \{HD, LD\}$ , which map to high and low disclosure respectively.<sup>16</sup>  $i$  receives the following payoffs for their choice  $j$ :

$$\pi_{ij} = v - c(j|\theta) \quad (1)$$

where  $c(j|\theta)$  is a reduced form reputational/brand equity costs of choosing action  $j$  given the type  $\theta$ . I impose the following restrictions on  $c(\cdot)$ :

- $c(LD|\theta_0) = 0$ , “low disclosure” of the organic type is costless
- $\frac{\partial c(HD|\theta)}{\partial \theta} < 0$ , high disclosure costs for low types are larger than for high types (and organic types)

Next, I consider the follower’s problem. Follower  $f$  is a risk-neutral agent, with payoffs:

$$u_f = \theta - v. \quad (2)$$

Assume follower’s outside option is normalized to utility 0. The equilibrium concept I will use for this model is perfect Bayesian equilibrium (PBE). Now, define a follower’s belief that a content is of type  $\theta$  given action  $j$  as:  $\mu_\theta(j) = Pr(\theta|j)$ ,  $\sum_\theta \mu_\theta(j) = 1$ . I make an assumption that reflects followers’ behavior in these settings:

**Assumption 1** *Followers believe that disclosures signal advertisements, i.e.  $\mu_0(HD) = 0$*

The game proceeds as follows. The influencer moves first, exogenously realizing  $\theta$  and choosing disclosure choice  $j$ . Followers move second, observing the choice  $j$  and forming beliefs over the quality of the content  $\mu_\theta(j)$ . Followers then choose to pay  $v(j)$  that makes them indifferent between watching the content and the outside option.

### 3.1 Pooling Equilibrium

I now show that pooling equilibria exist in the model. Define  $p_L$  as the probability that  $\theta = \theta_L$ , and likewise  $p_H$  for  $\theta = \theta_H$ . Then, the optimal viewership choice for follower  $f$  when  $j = LD$  is:

$$v^* = (1 - p_L - p_H)\theta_0 + p_L\theta_L + p_H\theta_H \quad (3)$$

In the pooling equilibrium, we must specify the off-path beliefs, which is the belief when high disclosure is realized. With the help of Assumption 1, we have:

$$\begin{aligned} \mu_H(HD) &= \lambda, & \lambda &\in [0, 1] \\ \mu_L(HD) &= 1 - \lambda \end{aligned}$$

---

<sup>16</sup>One could also include an “advertisement payment term”, e.g.  $a * 1\{\theta \in (\theta_L, \theta_H)\}$  to the influencer payoffs that reflects the payment an influencer would receive when they produce sponsored content. Adding such a term does not change the analysis, so is omitted for simplicity.

We also need high disclosure costs to be sufficiently high compared to low disclosure:

$$c(HD|\theta) - c(LD|\theta) > Q, \forall \theta \quad (4)$$

Under these conditions, we have the following pooling equilibrium lemma:

**Lemma 1** *A pooling equilibrium where  $j = LD$  for every  $\theta$  exists*

See Appendix A.1 for the proof.

In pay-for-placement settings, we see this pooling equilibrium as the usual outcome. The explanation for not seeing voluntary disclosure is that costs of disclosing are high. For shows and movies, the costs of disclosure are high because disclosing might ruin exciting moments or degrade the perceived quality of the show overall. In the payola example, the costs of disclosure for the radio DJ were astronomically high for two reasons. First, there was a massive reputational effect of being labeled a “sellout.” Radio shows of payola affected DJs were cancelled or became much less popular after Congressional trials - even when there wasn’t enough proof that DJs were accepting undisclosed payments. Second, reading disclosures forced breaks in the music and sounded like advertisements, making the radio show much less palatable to listeners.

### 3.2 Separating Equilibrium

Now I define conditions for a separating equilibrium. Define  $\mu_H(j), \mu_L(j)$  as the belief that follower  $f$  holds about the probability that content is  $\theta_H, \theta_L$  respectively:  $\mu_H(j) = Pr(\theta = \theta_H|j)$ ,  $\mu_L(j) = Pr(\theta = \theta_L|j)$ . The separating equilibrium this case signals quality. So  $j = LD$  if  $\theta = \theta_L$  and  $j = HD$  if  $\theta = \theta_H$ .

$$\begin{aligned} \mu_H(LD) &= 0, & \mu_H(HD) &= 1 \\ \mu_L(LD) &= \lambda_L, & \mu_L(HD) &= 0 \end{aligned}$$

Optimal viewership and payoffs for the choices are:

$$v^*(LD) = (1 - \lambda_L)\theta_0 + \lambda_L\theta_L \quad (5)$$

$$\pi^*(LD) = (1 - \lambda_L)\theta_0 + \lambda_L\theta_L - c(LD|\theta) \quad (6)$$

for the choice of low disclosure,  $j = LD$ . For high disclosure,  $j = HD$ , the payoffs are:

$$v^*(HD) = \theta_H \quad (7)$$

$$\pi^*(HD) = \theta_H - c(HD|\theta) \quad (8)$$

Two more conditions are needed: one that says that the reputational effects of a high disclosing low type is sufficiently larger than a low disclosing low type:

$$c(HD|\theta_L) - c(LD|\theta_L) > M \quad (9)$$

and another condition that says the reputational effects of a high disclosing high type isn't that bad when compared to low disclosing high types:

$$0 < c(HD|\theta_H) - c(LD|\theta_H) \leq N$$

Recall from the first part that if  $c(HD|\theta_H) - c(LD|\theta_H)$  was sufficiently large then there would be a pooling equilibrium. Thus, we must make sure that the difference in costs must be less than the minimum of the two conditions:

$$0 < c(HD|\theta_H) - c(LD|\theta_H) \leq \min\{N, Q\} \quad (10)$$

**Lemma 2** *A pooling equilibrium where  $\theta_H$  types always choose HD and types  $\theta_L, \theta_0$  always choose LD exists.*

See Appendix A.2 for the proof.

Contexts in which placements are considered advertising more frequently end up in this equilibrium. Search advertising is an example where disclosure becomes a way for firms to differentiate themselves from others. A relevant study is Sahni and Nair (2020a) who observe a signaling effect in search ads, whereby higher quality companies pay to advertise to consumers conducting searches, and the disclosure acts as a signal of their quality, resulting in increased business.

From this simple exercise, we can see how pooling and separating equilibria can help discern whether a marketing context leans towards product placement or advertising. The existence of these equilibria is entirely determined by disparities in the cost of disclosure for higher quality brands. To examine this further, I utilize empirical data to assess whether influencer marketing aligns more closely with placement or promotion.

### 3.3 Testable Implications

My simple theoretical model provides some testable implications from data. Because voluntary disclosure exists in my setting, it is more likely for influencer marketing on Twitch to be in a separating equilibrium. The testable implications for a separating equilibrium are the following:

1.  $v^*(HD) > v^*(LD)$  if  $\theta_H \geq \theta_0$ : Viewership for high disclosure streams should be higher than low disclosure streams (including organic streams) as long as high quality sponsored content is no worse than organic content.
2.  $c(HD|\theta_L) - c(LD|\theta_L) > c(HD|\theta_H) - c(LD|\theta_H)$ : it is more reputationally costly for low types to disclose than high types.

3.  $v(HD|\theta_L) > v(LD|\theta_L)$ : When a low type discloses in the separating equilibrium, we should expect viewership to increase temporarily because of the off-path beliefs.

## 4 Descriptive Results

In this section, I present descriptive evidence that aims to achieve two objectives. First, the descriptives test the predictions made by the theory model, providing support for advertising mechanisms predominantly driving influencer marketing decisions. Second, the descriptives help justify various decisions made in formulating the structural model. I show that sponsored game dev streams are associated with lower concurrent viewership and fewer new followers compared to organic content. Lower ACV is a short term cost that decreases the Twitch-ad and donation revenue for a particular stream, and fewer followers decreases future viewership, leading to less Twitch and sponsor incomes in the future. I use an instrumental variables regression to recover unbiased estimates of the effects of disclosure. I then construct a measure of “brand alignment” using qualitative video game data and streamers’ histories to show that streamers select into high disclosure when video games are well-aligned. Lastly, I provide evidence supporting forward-looking behavior by streamers.

### 4.1 High disclosure has higher viewership

I run OLS regression with ACV and new followers as my dependent variable of interest on stream-game level data with the specification:

$$Y_{it} = \gamma_0 + \gamma_a ad_{it} + \gamma_d HD_{it} * ad_{it} + \gamma_x x_{it} + \nu_i + \tau_t + \xi_{dev} + \varepsilon_{it} \quad (11)$$

for influencer  $i$  and stream observation  $t$ .  $Y$  is an outcome of interest, such as ACV or net follower change during the stream-game observation;  $ad$  is the indicator for a sponsored demo stream;  $HD_{it}$  is high disclosure of the stream;  $x_{it}$  includes time-varying observable characteristics of streams, games, and influencers;  $\nu_i$  is an influencer fixed effect;  $\tau_t$  are quarter-year and day-of-week related fixed effects; and  $\xi_{dev}$  are game developer fixed effects. Results of the regression are in columns 1 and 2 of Table 3. I run a similar regression to equation 11, except I subset just the sponsored game dev observations. Results of this regression are displayed in columns 3 and 4 of Table 3. The regressions imply that game dev sponsors decrease ACV by  $\approx 6\%$  and the number of followers acquired by  $\approx 50\%$ . Even though I do not control for selection into sponsored content, institutional detail supports the idea that the OLS measurements are some sort of upper bound. Streamers should always be trying to maximize ACV when making sponsored content, because embedded ads and donations are positively correlated with it. Streamers are also in some sort of repeated game with potential sponsors; if a sponsor can see that streamers have shirked/sabotaged sponsored content efforts in the past, they would be hesitant to reach out to said streamer. Given these arguments, the treatment effect of an experiment where streamers were randomly assigned and

forced to produce sponsored content would likely produce much more negative effects.

When streamers choose high disclosure, their viewership increases 13% over low disclosure, and 7% over organic content. Focusing on the sample of only game dev streams, high disclosure is correlated with a still significant, but smaller 6% increase in viewership versus low disclosure. In both samples, the change in the number of followers acquired is not statistically significant. These regression outputs are consistent with the first testable implication from the theoretical model: if high types are about as good as organic types, high disclosure outperforms low disclosure and organic streams in a separating equilibrium.

## 4.2 Costs of high disclosure is lower for high types

The second testable implication suggests that the costs of high disclosure should be lower for high types in a separating equilibrium. I use the change in the number of followers as a proxy for sponsorship and disclosure costs. In equilibrium, there are costs of disclosure that are unobserved, which makes this comparison difficult. For example, if  $\theta_H$  types only disclose, then the cost of low disclosure for  $\theta_H$  is not observed. Conversely,  $\theta_L$  types never disclose, so the cost of high disclosure for  $\theta_L$  is also unobserved.

	High Disclosure	Low Disclosure
$\theta_L$	$c(HD \theta_L)$ : Comparing IV + OLS coefs and $\frac{\partial c(HD \theta)}{\partial \theta} < 0$ assumption IV coef “game dev spon hi disc” is lower bound.	$c(LD \theta_L)$ : assume $c(LD)$ is constant regardless of $\theta$ . OLS regression coef for “game dev sponsor”
$\theta_H$	$c(HD \theta_H)$ : OLS coefs smaller magnitude than IV coefs and $\frac{\partial c(HD \theta)}{\partial \theta} < 0$ $\theta_H$ selects into $HD$ in equilibrium. OLS coefs “game dev sponsor” + “game dev spon hi disc”	$c(LD \theta_H)$ : assume $c(LD)$ is constant regardless of $\theta$ . OLS regression coef for “game dev sponsor”

Table 4: Recovering disclosure costs

To get around these challenges, I make use of one assumption and an instrumental variables (IV) method. The strategy I employ is described in Table 4. I assume that  $c(LD|\theta_H) = c(LD|\theta_L)$ , which can be interpreted as obfuscation costs of sponsored content is independent of type. This assumption seems relatively innocuous; the quality of the sponsor should only affect reputation when the sponsorship is disclosed, not when it is obfuscated. Furthermore, followers punish hiding sponsorships regardless of how “good” the sponsor is. This enables me to interpret the “game dev sponsor” coefficient in Table 3 as  $c(LD) = c(LD|\theta) = 0.65$ .

I observe the some biased measure of  $c(HD)$  in the OLS regression in the OLS regression as the sum of the “game dev sponsor” and “game dev spon hi. disc.” coefficients. However, under a separating equilibrium, the decision to disclose is clearly endogenous, as omitting  $\theta$  from Equation 11 means the disclosure decision is correlated with the error term. I instrument for the disclosure decision using the instrument: how often is a sponsored game disclosed by other influencers within the past thirty days. That is, for influencer  $i$  playing game  $g$  at day  $t$ , the instrument is:

$$z_{it} = \frac{\sum_{j \neq i} \sum_{\tau=t-30, \dots, t-1, t} HD_{j\tau} * ad_{j\tau} * 1\{g_{j\tau} = g_{it}\}}{\sum_{j \neq i} \sum_{\tau=t-30, \dots, t-1, t} ad_{j\tau} * 1\{g_{j\tau} = g_{it}\}} \quad (12)$$

Relevance for this instrument comes from the idea that the disclosure decision may be exogenously given by the game developer for a particular marketing campaign. The instrument tries to proxy the directive to disclose from the developer by looking at other influencers who may be in the same campaign. One threat to exclusion may be that marketing campaigns can affect viewership outside of disclosure. I attempt to control for this threat by including a control that counts the number of instances a game is observed in the past week, the idea being that any other marketing efforts would be captured by a collective supply-side response from streamers to cash in on the temporary increase in probability.

First stage F:	-	-	-	-	63.5

Table 5: IV Regressions; standard errors in parenthesis clustered at influencer level. Influencer characteristics include number of followers and most frequently played game. Game characteristics include game age genres, themes, and game modes. Stream characteristics include stream length, drops, tournament, championship, giveaway, charity, subathon, and first game of the day

Under some restrictive assumptions like homogeneous treatment effects?, we can interpret the coefficient on “Game dev spon hi. disc.” in column 4 of Table 5 as the effect of high disclosure on reputation overall, implying that  $c(HD) = 1.48$ . Given the restriction that  $c(HD|\theta)$  decreases in  $\theta$ , we know  $c(HD|\theta_L) > c(HD|\theta_0)$  and  $c(HD|\theta_L) > c(HD|\theta_H)$ . Importantly, the OLS regression suggests that whoever selects into  $c(HD)$  in equilibrium realizes costs between (0.468, 0.685). My OLS specification (Equation 11) rules out the disclosure of organic content, so it must be  $\theta_H$  types selecting into disclosure in equilibrium. Thus, my IV estimate of  $c(HD)$  is a lower bound on  $c(HD|\theta_L)$ . This is a larger estimate than  $c(LD|\theta_L)$  from the OLS regression so that the difference in costs between high and low disclosure is much higher for  $\theta_L$  types than for  $\theta_H$  types. These findings are consistent with the second testable implication of a separating equilibrium where only high types disclose.

### 4.3 Viewership is higher in off-path equilibrium

The final testable implication that a separating equilibrium with signaling high types imply is that when low types deviate, the initial off-path equilibrium response results in a positive viewership shock. This is indeed true in my setting. Column 2 of Table 5 shows that the unbiased measurement of high disclosure on viewership is positive when pooling all types. The point estimate is even larger than the OLS estimate in the column 1, which is under an environment when only  $\theta_H$  types are disclosing in equilibrium. This positive measurement can be attributed to consumers treating high disclosure streams as high types, so when off-path equilibrium beliefs have not updated, we should expect a  $\theta_H$  type viewership responses even for high disclosure  $\theta_L$  type streams. The IV regression does exactly this, as it recovers the effect of high disclosure on viewership without changing any other features in the environment.

### 4.4 Selection on unobserved quality

I provide more data-driven evidence that streamers are choosing disclosure levels based on sponsor type. The theoretical model treats sponsor type as a pure vertical quality, but that might not be the case in practice. “High type” sponsors also depend on the horizontal match value - a kid-friendly streamer may not want to play any type of horror game no matter how good the vertical quality of the game/game developer might be.

I construct a proxy metric for this horizontal aspect of sponsor type or “alignment” by using qualitative characteristics of video games. The IGDB data comes with details about genres/themes/keywords of almost all video games seen on Twitch. I am able to compute, at every observational period, the prior frequency of genres and themes of games that a streamer has previously played. As an example, at the eleventh observation of a streamer, if the streamer has played platform games 9 out of the previous 10 observations I assign a value 0.9 to the platform genre.<sup>17</sup> There are 23 unique genres, 22 unique themes, and 6 unique game modes in the IGDB data, so at each observation a streamer’s type is the 54-vector (including no genre, no theme, and no game mode) of prior frequencies. I can then compute the correlational coefficient between the 54-vector of genres for each game and the 54-vector of historical frequencies for each streamer to obtain a single number on the interval  $[0, 1]$  representing the “alignment” between streamer and game at a specific time period.

Some streamers brand themselves as being “variety” streamers; these streamers build their followings by playing all sorts of wacky games. For such variety streamers, how similar current games are compared to games played previously may not be a great proxy for alignment since these streamers intentionally look for novelty. To address this concern, I subset streamers who have played less than 12 unique video games, which is the 25th percentile (see Table 1) of unique games played across all streamers in my data. Their revealed preference for just a few games strongly speaks to what they enjoy and what their audience expects from them. The metric is

---

<sup>17</sup>A game can be a part of multiple genres

more suitable with my focal subset of streamers where good sponsor alignment is more precisely defined by historical preferences.

Figure 3 plots the cumulative distribution function of genre similarities by disclosure level: The

Figure 3: CDFs of genre+theme+mode similarity by disclosure level, streamers with  $\leq 12$  unique games played

green CDF line is close to the red CDF line meaning that among this subset of streamers, the profile of games played during high disclosure streams is very similar to the profile of games played than games played during organic streams. Most of the mass is towards the right, indicating that high disclosure sponsored games are quite similar to the historical composition of games played by streamers. Meanwhile, the blue CDF representing low disclosure games has much more mass to the left, implying that streamers try to hide dissimilar sponsors. I interpret this finding as evidence for selection into high disclosure on brand alignment. Obfuscating poorly aligned games makes sense - streamers can hide poorly aligned sponsors to the fullest extent they are allowed to instead of obviously appearing as a “sellout.” When the sponsored game is better aligned, streamers are more willing to prominently disclose because the game is better suited to their expertise and/or their audience’s taste.

From these descriptive exercises, I conclude that influencer marketing is similar to advertising because influencers and brands care to leverage advertising mechanisms like signaling. Were influencer marketing just placement, we would not observe behavior attempting to make the sponsor more conspicuous.

## 4.5 Influencers are forward looking

Streamers have provided anecdotal evidence claiming that game developers are willing to pay up to \$1 per viewer for creating sponsored content. For a 10,000 ACV streamer, this translates to anywhere between \$100 to \$10,000 an hour, with offers more likely to be on the higher side of the range. Comparatively, income from donations, Twitch ads, and subscriptions total around \$20,000 per month for a 10k ACV streamer.<sup>18</sup> Sponsored content clearly pays much better than that of organic content, yet only 1.8% of stream-game observations are sponsored. Conversations with talent management agencies reveal that the most popular streamers (such as the ones studied in this paper) generally have an abundance of sponsors to choose from, and that the majority of potential sponsors are rejected. If streamers only care about maximizing short-run profits and are truly myopic, the optimal decision would be to accept more of these sponsors and create sponsored content every day.

## 5 Model

I develop a structural model that extends the static, one period signaling model into an infinite horizon dynamic discrete choice model. The goal of the model is to quantify the impact of a strict disclosure counterfactual policy.

My model takes place in a discrete time; in each period  $t$ , influencer  $i$  makes a decision on what to stream, if anything. A sponsored game exogenously arrives each period carrying a brand match value,  $\theta$ , which the influencer observes but is unobservable to the econometrician. This is analogous to the sponsor “type” and can be thought of as a hidden/unobserved state. With the sponsor in hand, an influencer has four actions they can take,  $j \in \{HD, LD, N, 0\}$ , corresponding to high disclosure sponsor, low disclosure sponsor, normal stream, and no stream respectively. In the signaling model, the influencer is bound to the  $\theta$  realized exogenously. Here, they have the decision between a sponsored type and the organic type. I am implicitly assuming that an influencer always has a sponsor to choose for each stream in addition to organic content. This assumption seems somewhat reasonable given that I am studying more mature streamers who can always pick up a crappy mobile game to advertise.

I introduce a parametric form for viewership  $v$  which is dependent on  $\theta$ , endogenous, and exogenous state variables. The level of disclosure affects viewership, which enters directly into the influencer’s utility function and affects choices. I augment the utility function with additional variables to help the model rationalize influencer choices at different states. To finish the specification, I introduce structure to the reduced form “reputation” costs  $c(j|\theta)$ . These costs now are realized in the dynamics; by defining parametric transition functions for the endogenous states, choices  $j$  and types  $\theta$  affect future realizations of endogenous states, thereby changing future payoffs and choices.

---

<sup>18</sup>All of these numbers are from a DisguisedToast video, where some finances of streaming are discussed: [https://www.youtube.com/watch?v=6m5P\\_n5njCQ](https://www.youtube.com/watch?v=6m5P_n5njCQ)

## 5.1 State Variables

### 5.1.1 Exogenous Variable Selection

The descriptive regressions leveraged many covariates such as stream length, game dummies, and more. A dynamic model cannot feasibly incorporate so many variables, as the decision maker must integrate over all possible combinations of these covariates in future periods to calculate their value function. To deal with such issues, I perform two simplifications. First, I aggregate the stream-game level observations up to a daily level since I do not need stream or game specific characteristics anymore. I sum up the length of stream for a day and let the sponsorship (high disclosure) indicator equal 1 if any stream-game combination during the day was a sponsored stream (prominently disclosed). Second, I simplify my universe of covariates into two exogenous states and one endogenous state. Endogenous states are affected by the influencer’s decisions at each period; the probability of reaching a state in future periods depends on decisions made today. Exogenous states are not affected by the influencer’s decisions in previous periods; states are realized with the same probability each period, regardless of past actions.

The two exogenous states are  $x_{it} = (\theta_{it}, h_{it})$ , where  $\theta$  is the unobserved match quality and  $h$  is the number of hours streamed. The unobserved match quality  $\theta$  is assumed to be discrete; it is either a high match quality  $\theta_H$  with probability  $p_H$  or a low match quality  $\theta_L$  with probability  $p_L = 1 - p_H$ . I assume that this arrives exogenously each period for estimation purposes.

I restrict  $h$  to be on a discrete grid on  $[1, 15]$  with increments of 1. In my data, over 95% of daily observations are live for under 15 hours. The empirical distribution for daily hours streamed given  $HD, LD$  or  $N$  are fairly similar regardless of content choice. The number of hours streamed is independently drawn each period from the empirical distribution.

### 5.1.2 Endogenous State Variable

I assume that the endogenous state variable  $f$  is discretized on a grid from 10.5 to 15 with an interval of 0.5.  $f$  is analogous to the number of log followers I observe in the data. Much of the sample lies in this range. The discretization helps compute conditional choice probabilities and value functions. To obtain CCPs/value functions for any value not on the grid, I use a gridded linear interpolation. The transition of  $f$  between two time periods takes on the form:

$$f_{i,t+1} = \log \left( \exp(f_{it}) + \phi_j(x_{it}, f_{it}, \eta_{it}) \right) \quad (13)$$

$\phi_j(\cdot)$  is a function that computes the change in followers at time  $t$ , and  $\eta$  is a mean zero i.i.d shock to follower change that is unobserved to the econometrician and to the influencer before the

decision is made. I impose a functional form on  $\phi$ :

$$\begin{aligned} \phi_j(x_{it}, f_{it}, \eta_{it}) = & \sinh \left( \omega_{0j} + \omega_f \underbrace{f_{it}}_{\text{followers}} + \omega_h \underbrace{h_{it}}_{\text{hours}} + \omega_a \underbrace{1\{j = HD, LD\}}_{\text{ad}} + \right. \\ & \left. (\omega_d + \omega_{d\theta}\theta_{it}) \cdot 1\{j = HD\} + \eta_{it} \right) \end{aligned} \quad (14)$$

where  $\sinh$  is the hyperbolic sine function.<sup>19</sup> Equation 14 is the model analog to the OLS regressions in columns 2 and 4 of Table 3, where the change in followers on the left hand side of the equation is in terms of IHS. I use  $\sinh$  to invert IHS followers change into levels. Followers can never be negative, so I bound  $f$  below by 1. The follower change from no stream,  $\phi(0, \cdot)$ , is normalized to zero. Crucially,  $\phi$  depends on the hidden state,  $\theta$ , which affects the follower transition only when the influencer chooses high disclosure. If the influencer chooses  $HD$  with a good quality brand match  $\theta_H$ , they get a follower signaling boost  $\omega_{d\theta}$ .

## 5.2 Utility

Each influencer has the indirect utility function

$$u_{ijt} = \underbrace{r_j(f_{it})}_{\text{util of streaming}} + \underbrace{\alpha_j(f_{it})}_{\text{util of ad}} + \underbrace{\beta_v v_j(h_{it}, f_{it}, \theta_{it})}_{\text{viewership util}} + \varepsilon_{ijt} \quad (15)$$

where  $h_{it}$  is the log stream length, an exogenous state.  $f_{it}$  is the number of log followers the influencer has at time  $t$ .  $v_j(h, f, \theta)$  is log average concurrent viewership (ACV)<sup>20</sup> conditional on action  $j$ . This number is observed in the data, but I will assume a functional form to allow us to conduct counterfactual simulation.  $\beta_v$  converts ACV into utility terms. We can interpret  $\beta_v v_j(\cdot)$  as the utility equivalence of revenue earned from streaming, which includes donations and Twitch ad income discussed in Section 2.  $\alpha_j(\cdot)$  is the utility from advertising, which I allow to depend on the follower state  $f$ , and  $r_j(\cdot)$  is the utility of streaming which also depends on  $f$ .  $\varepsilon_{ijt}$  is a nested logit utility shock, where the sponsored content decisions  $\{HD, LD\}$  share a nest. Organic content and no stream are each in their own nests.

$\alpha_j$  is equal to 0 when  $j \in \{N, 0\}$  and takes on the linear functional form:

$$\alpha_{ijt} = \alpha_0 + \alpha_\theta * \theta_{it} + \alpha_f f_{it} \quad (16)$$

for  $j \in \{HD, LD\}$ . These functional form assumption comes from conversations with various influencer management agencies. As mentioned in Section 2.1, streamers are offered compensation based on a primitive pricing “calculator.” I allow the baseline level of utility for advertising to

<sup>19</sup> $\sinh x = \frac{e^x - e^{-x}}{2}$

<sup>20</sup>Throughout this section I may use the term “viewership,” but that strictly refers to ACV in this setting

change depending on the brand alignment  $\theta$ . The idea is that streamers should be happier playing video games they are well aligned with. There are various nuances like discounts for long-term sponsorships that we abstract away from. It is important to note that  $\theta$  affects both sponsorship utilities here, unlike in the follower transition.

Similarly,  $r_j = 0$  if  $j = 0$ . Else,

$$r_{ijt} = r_0 + r_f f_{it} \quad (17)$$

$r_j$  changes the attractiveness of the outside option as a function of the number of followers. In the data, streamers choose the outside option with a similar frequency whether they are small or large.  $r_f f_{it}$  is necessary to counteract the fact that larger streamers will command a higher ACV and thus obtain more viewership utility through  $\beta_v v(\cdot)$ . Without this functional form, the outside option gets less attractive the larger the streamer, which is inconsistent with the data. Another reason why this may be a reasonable functional form is that more popular streamers may embark on other business ventures or simply want to enjoy their celebrity status, both of which make streaming less attractive.

Finally, I parameterize  $v_j(\cdot)$  as the following log-log ACV model:

$$v_j(h_{it}, f_{it}, \theta_{it}) = \phi_{0i} + \underbrace{\phi_h h_{it}}_{\text{hours}} + \underbrace{\phi_f f_{it}}_{\text{followers}} + \underbrace{\phi_a 1\{j = HD, LD\}}_{\text{ad}} + (\phi_d + \phi_{d\theta} \theta_{it}) 1\{j = HD\} + \nu_{ijt} \quad (18)$$

This linear ACV model captures the key effects that stream length, disclosure, and followers have on ACV. This is the model analog to the OLS regressions in columns 1 and 3 of Table 3 and very similar in spirit to the follower transition in Equation 13.

## 6 Estimation

The main challenge in the estimation is that brand alignment,  $\theta$ , is observed by the streamer but not the econometrician.  $\theta$  affects ACV  $v_j$ , a per period output, and the follower transition  $\phi_j$ . Therefore, the standard conditional independence assumptions are violated.<sup>21</sup> This precludes simpler dynamic discrete choice estimation methods as in Rust (1987) or Hotz and Miller (1993). The nested fixed point algorithm is computationally intensive, while standard two-step methods cannot be used since unobserved states affect choices and transitions.

Instead, I proceed using the two step method described in Section 6 of Arcidiacono and Miller (2011), where in the first step I estimate the conditional choice probabilities jointly with the distribution of unobserved  $\theta$ , viewership parameters ( $\gamma_v = [\phi, \nu]$ ), and the follower transition ( $\gamma_f = [\omega, \eta]$ ) using an expectation maximization (EM) algorithm. In the second stage, the flow utility parameters are recovered using forward simulation as in Hotz et al. (1994) and Bajari et al. (2007).

---

<sup>21</sup>see Aguirregabiria and Mira (2010), assumptions CI-X and CI-Y

The full likelihood of observing the data has three components:

$$L = \text{Likelihood of viewership} \times \text{Likelihood of follower transition} \times \text{Likelihood of choices}$$

However, unobserved brand alignment affects all three components of the likelihood, so joint estimation of the ACV, follower transition, and choice is computationally burdensome. For each fixed candidate vector of parameters, the value function must be iterated to convergence. To help reduce computation complexity, I use the i.i.d nature of  $\theta$  and use the two step CCP estimator in Arcidiacono and Miller (2011) which will be described below.

## 6.1 The AM two-step estimator

### First stage

I now describe the first stage of the Arcidiacono and Miller (2011) estimator. Let  $\gamma^{(1)} = [\gamma_v^{(1)}, \gamma_f^{(1)}]$  be the initial guess of viewership and follower transition parameters. Let  $p^{(1)}$  be the initial guess of conditional choice probabilities. Lastly, let  $\pi^{(1)}(\theta)$  be the initial guess of the distribution of the unobserved state,  $\theta$ .

At iteration  $m$ , update the following objects in the specified order:

1. Compute the conditional probabilities of being in each unobserved state,  $q_{i\theta t}^{(m+1)}$

$$\underbrace{q_{i\theta t}^{(m+1)}}_{N \times |\theta| \times T} = \frac{L_{it}^{(m)}(\theta_{it} = \theta)}{L_{it}^{(m)}} \quad (19)$$

where  $L_{it}$  is the full likelihood of the data on  $i$  at time  $t$ , and  $L_{it}(\theta_{it} = \theta)$  is the joint likelihood of the data and unobserved state  $\theta$  occurring at time  $t$ . These likelihoods are evaluated at the current iteration of parameters  $\gamma^{(m)}$ , distribution of unobserved states  $\pi^{(m)}(\theta)$ , and conditional choice probabilities  $p^{(m)}$ . Because of the exogenous  $\theta$  assumption, this is a simple calculation and should not run into numerical underflow or other instability issues.

2. Next, I compute the distribution of the unobserved states  $\pi^{(m+1)}(\theta)$ :

$$\pi^{(m+1)}(\theta) = \frac{1}{NT} \sum_i \sum_t q_{i\theta t}^{(m+1)} \quad (20)$$

3. With  $q_{i\theta t}^{(m+1)}$  computed, the conditional choice probabilities can be updated using the data:

$$p_{jt}^{(m+1)}(f, \theta) = \frac{\sum_i \sum_t d_{ijt} q_{i\theta t} I(f_{it} = f)}{\sum_i \sum_t q_{i\theta t} I(f_{it} = f)} \quad (21)$$

4. Now the maximization step; the updated viewership and follower transition parameters

$\gamma^{(m+1)} = [\gamma_v^{(m+1)}, \gamma_f^{(m+1)}]$  maximizes the lower bound of the likelihood:

$$\begin{aligned} \gamma_v^{(m+1)}, \gamma_f^{(m+1)} = \arg \max_{\gamma_v, \gamma_f} & \sum_i \sum_t \sum_{\theta} \sum_j q_{i\theta t}^{(m+1)} \\ & \times d_{ijt} \left[ \log(p_{jt}^{(m+1)}(f_{it}, \theta_{it})) + \log(nf_{jt}(x_{it}, f_{it}, \theta_{it}|\gamma_f)) \right. \\ & \left. + \log(v_{jt}(x_{it}, f_{it}, \theta_{it}|\gamma_v)) \right] \end{aligned} \quad (22)$$

I iterate the steps above until convergence, which is reached if the relative change in the maximized log likelihood from equation 22 between sequential iterations is less than  $1e-6$ .

## Second stage

In the second stage, the parameters from the flow utility (equation 15) are recovered using forward simulation. Starting from each state-action pair (including unobserved states), the path of all state variables and decisions are simulated significantly out into the future. The discounted sum of utilities is obtained from each path, and the conditional value function is computed by taking the means over all paths starting at each state-action pair. Once the conditional value functions are obtained, one can compute the implied conditional choice probabilities given the T1EV assumption in the flow utility. A minimum distance estimator can be constructed between the CCP from the first stage and the simulated CCP from the second stage.

Arcidiacono and Miller (2011) provides a method of moments estimator to recover the utility parameters, given the T1EV assumption on the unobservables. For the organic stream choice,  $N$ , difference between its choice-specific value function and the outside option choice 0 is:

$$\tilde{v}_N(f_{it}, \theta_{it}) - \tilde{v}_0(f_{it}, \theta_{it}) = \log(\hat{p}_N(f_{it}, \theta_{it})) - \log(\hat{p}_0(f_{it}, \theta_{it})) \quad (23)$$

$\tilde{v}_j(f_{it}, \theta_{it})$  are the simulated conditional value functions from the second stage, and are a function of the flow utility parameters.  $\hat{p}_j(f, \theta)$  is the conditional choice probability of choice  $j$  in state  $(f, \theta)$  from the converged first stage estimation. For either of the advertising choices,  $\{HD, LD\}$ , Lemma 3 in Arcidiacono and Miller (2011) implies the following relationship:

$$\begin{aligned} \tilde{v}_j(f_{it}, \theta_{it}) - \tilde{v}_0(f_{it}, \theta_{it}) = \\ \rho_{nest} \log(\hat{p}_j(f_{it}, \theta_{it})) + (1 - \rho_{nest}) \log(\hat{p}_{HD}(f_{it}, \theta_{it}) + \hat{p}_{LD}(f_{it}, \theta_{it})) - \log(\hat{p}_0(f_{it}, \theta_{it})), \end{aligned} \quad (24)$$

$j \in \{HD, LD\}$

where  $\rho_{nest}$  is the nesting parameter measuring correlation between the nested logit shocks for the sponsored content choices. The moment estimator is formed by stacking the  $J - 1$  mappings for each observed and unobserved state:

$$\begin{pmatrix}
v_{HD}(f_0, \theta_0) - \tilde{v}_0(f_0, \theta_0) - (\rho_{nest} \log(\hat{p}_{HD}(f_0, \theta_0)) + (1 - \rho_{nest}) \log(\sum_{j \in \{HD, LD\}} \hat{p}_j(f_0, \theta_0)) - \log(\hat{p}_0(f_0, \theta_0))) \\
v_{LD}(f_0, \theta_0) - \tilde{v}_0(f_0, \theta_0) - (\rho_{nest} \log(\hat{p}_{LD}(f_0, \theta_0)) + (1 - \rho_{nest}) \log(\sum_{j \in \{HD, LD\}} \hat{p}_j(f_0, \theta_0)) - \log(\hat{p}_0(f_0, \theta_0))) \\
v_N(f_0, \theta_0) - \tilde{v}_0(f_0, \theta_0) - (\log(\hat{p}_N(f_0, \theta_0)) - \log(\hat{p}_0(f_0, \theta_0))) \\
v_{HD}(f_0, \theta_1) - \tilde{v}_0(f_0, \theta_1) - (\rho_{nest} \log(\hat{p}_{HD}(f_0, \theta_1)) + (1 - \rho_{nest}) \log(\sum_{j \in \{HD, LD\}} \hat{p}_j(f_0, \theta_1)) - \log(\hat{p}_0(f_0, \theta_1))) \\
\vdots \\
v_{HD}(f_1, \theta_0) - \tilde{v}_0(f_1, \theta_0) - (\rho_{nest} \log(\hat{p}_{HD}(f_1, \theta_0)) + (1 - \rho_{nest}) \log(\sum_{j \in \{HD, LD\}} \hat{p}_j(f_1, \theta_0)) - \log(\hat{p}_0(f_1, \theta_0))) \\
\vdots
\end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ \vdots \\ 0 \\ \vdots \end{pmatrix} \quad (25)$$

Where  $f_0$  is the first follower state on its ordered grid,  $\theta_0$  is the first unobserved state on its ordered grid, etc. Minimizing the squared weighted sum of the above vector with respect to the utility parameters recovers the remaining structural parameters.

## 6.2 Identification

Table 6 provides a summary of variation in the data that allows for the identification of parameters in my structural model. Here, I will provide a more detailed discussion. I will first discuss identification of first stage parameters, which include the state transition parameters  $\omega$  from Equation 13 and the viewership parameters  $\phi$  from Equation 18. The identification argument for both sets of parameters are identical, so for exposition I will focus on just the state transition parameters. The number of new followers obtained in each period,  $nf_{it}$ , is observed in the data, and for every  $i, t$  observation, there is variation in hours streamed  $h_{it}$ , follower count  $f_{it}$ , and the choice decision  $j$ . Given the linearity assumptions, the parameters in the first line of the equation are easily identified. The unobserved state is assumed to be observed during the EM algorithm step, so we can compute the coefficients related to high disclosure.

The distribution of  $\theta$  is identified by correlation between disclosure choice, ACV, and new followers, as well as the linear functional form and distributional assumptions on  $nf$  and  $v$ . The intuition is as follows: if alignment has positive synergy with disclosure, then high disclosure observations will on average have higher ACV and more positive follower change metrics than a typical low disclosure sponsored stream. If a high disclosure observation fits this description, then the EM step will place a large posterior probability on the observation being in the well-aligned state. The frequency with which such observations occur gives the variation necessary to estimate the frequency that a well aligned sponsor arrives. The Bernoulli distributional assumption on  $\theta$  means a single parameter defines the distribution of the unobserved state.

Identification of second stage utility parameters are discussed next. Utility parameters governing the attractiveness of streaming (Eq. 17) are discussed in Section 5. To recap, streamers attract more followers as they grow, which translates into higher ACV. More ACV means more money and more utility for streamers, yet I observe that the share of the outside option of no stream remains relatively constant. The consistent quality of the outside option regardless of state identifies the parameters. I observe that larger streamers tend to advertise more, which increases the attractiveness of choosing

Parameter	Interpretation	Size	Variation
<b>Panel A: First stage parameters</b>			
$\phi$	Viewership (ACV) parameters	5	Observed ACV
$\omega$	Follower transition	5	Observed change in followers
$\phi_d, \phi_{d\theta}, \omega_d, \omega_{d\theta}$	Parameters related to disclosure	4	Distributional assumption on error terms (Eq. 14, 18) + Variation in observed ACV/follower transition conditional on <i>HD</i> or <i>LD</i> choice ( $\theta$ assumed observed in EM step)
$p(\theta)$	Unobserved state distribution	1	Correlation of choice, ACV, and new followers + functional form assumption on follower change (Eq. 14) and ACV (Eq. 18) + distributional assumption on $\theta$
CCPs	Conditional choice probabilities	80	Identified by choices in each bin ( $j \times f \times \theta$ ) and long panel of data (see Arcidiacono and Miller (2011))
<b>Panel B: Second stage parameters</b>			
$\alpha$	Sponsor utility parameters	2	Sponsorship frequency conditional on follower states
$\alpha_\theta$	Utility parameters related to alignment	1	Differences in first stage conditional choice probabilities over the unobserved state + functional form of Equation 16
$r$	Streaming utility parameters	2	Streaming frequency conditional on follower states
$\beta_v$	ACV to utility conversion	1	Correlation between CCPs and ACV across the streaming extensive margin (stream vs no stream) and on the sponsorship intensive margin (high vs low disclosure)
$\rho_{nest}$	Sponsorship nest coefficient	1	Within nest shares across different state variables

Table 6: Identification of Choice Model Parameters in Data

one of the sponsorship choices ( $j \in \{HD, LD\}$ ). This allows me to identify some advertising utility parameters in equation 16. The advertising alignment utility parameter ( $\alpha_\theta$ ) is identified by the difference in the first stage CCPs across the hidden states. Alignment affects both high and low disclosure utility, but only affects high disclosure observables - ACV and follower change - so the difference in low disclosure frequencies between the hidden states identifies the parameter.  $\beta_v$  is identified by the correlation between CCPs and ACV on the extensive margin of streaming (stream vs no stream) and the intensive margin of sponsorship (high vs low disclosure) conditional on  $\theta$ . On the extensive margin of streaming, if streamers with higher ACV choose stream more, then we know that the direction of this parameter must be positive. The intensive margin of sponsorship affects ACV but no other component of utility, so repeated observations of high vs low disclosure conditional on  $\theta$ , followers, and hours streamed pins down the level of  $\beta_v$ .

Lastly,  $\rho_{nest}$  is the nesting coefficient for the nested logit errors in the utility function (Eq. 15). In a static nested logit model, this parameter is identified by variation in the conditional shares of the within-nest goods over markets. In my single-market infinite horizon dynamic model, this variation cannot exist. There does exist variation of within-nest shares over different state variables, and this variation is enough to identify the nesting parameter.

## 7 Results and Counterfactuals

The data used in the estimation only runs until April 15, 2022. I am currently in the process of updating the structural model results to include the remaining data.

### 7.1 Estimation Results

Now I discuss the estimation results from the structural model. Table 7 presents the coefficients from the first stage estimation, and Table 8 presents estimated utility parameters from the second stage estimation.

New followers	Estimate	Std. error	ACV	Estimate	Std. error
$\omega_0$	-4.99	1.18	$\phi_0$	-1.46	0.42
$\omega_a$	-1.20	0.28	$\phi_a$	-0.14	0.06
$\omega_d$	-7.44	2.83	$\phi_d$	-0.77	0.34
$\omega_{d\theta}$	9.18	2.46	$\phi_{d\theta}$	1.19	0.14
$\omega_f$	0.69	0.09	$\phi_f$	0.70	0.03
$\omega_x$	0.51	0.11	$\phi_x$	0.04	0.04
$\sigma_\eta$	3.43	0.08	$\sigma_\nu$	0.99	0.02

$$P(\theta = \theta_H): 0.011 [0.008, 0.039]$$

Table 7: First stage new follower and viewership parameter estimates, bootstrap standard errors

Estimates from the first stage are consistent with the descriptive results. The characteristics related to a separating equilibrium are captured by the structural model. The coefficient  $\omega_a$  indicates

New followers	Estimate	Std. error
$\alpha_0$	-6.67	1.02
$\alpha_\theta$	2.14	0.70
$\alpha_f$	0.25	0.08
$r_0$	0.26	0.28
$r_f$	-0.11	0.10
$\beta_v$	0.19	0.14
$\rho_{nest}$	0.07	0.03

Table 8: Second stage utility parameter estimates, bootstrap standard errors

that creating sponsored content overall has a negative effect on follower change compared to organic content. Prominently disclosing a low quality brand ( $\omega_d$ ) creates a massive hit to the number of followers recovered. However, disclosing a good match ( $\omega_{d\theta}$ ) ends up increasing the net followers drastically versus a bad match, and even increases followers compared to organic content.<sup>22</sup> The direction of such effects are consistent with the findings from the IV regression (Table 5), supporting the separating equilibrium prediction that high types would have much lower reputation costs than low types. The large magnitudes can partially be explained by the fewer covariates in the structural model as well as the behavior of the IHS function, which takes on a much steeper slope near 0 and behaves similarly to the log function further out. Many sponsored content streams end up with new follower counts around zero, so sponsorship and disclosure decisions appear to have a very large impact.

ACV coefficients  $\phi$  follow a similar pattern, but are slightly smaller in magnitude. One inconsistency to note is that the effect of disclosing a low quality sponsor ( $\phi_d$ ) is negative in the structural model, whereas both the theoretical and the IV regressions predicted a positive effect. Off-path equilibrium beliefs explain this discrepancy; in the reduced form setting, the disclosure of low types is an off-path action which results in followers believing that the disclosed low type is actually a high type. Followers choose a higher level of viewership as a result of these beliefs. Conversely, the effect in the structural model is not an artifact of equilibrium objects. The structural model treats the effect of disclosure of low types as a primitive and is consistent with the true preferences of followers. In a counterfactual world where equilibrium adjusts to low types being prominently disclosed, intuition suggests that low types would command lower viewership.

Additionally, viewership in the theoretical model is an endogenous choice of followers, unlike follower change which is modeled as a given exogenous cost conditional on disclosure choice and type  $\theta$ . This may further explain why the structural model estimates for new followers are consistent with the theoretical predictions but viewership estimates are inconsistent.

The distribution of the unobservable state space  $\theta$  indicates that a well-aligned sponsor arrives just about 1.1% of the time. It is difficult for a sponsor to find a well-aligned influencer, and vice-versa. As a common sense check, recall that 1.8% of stream-game observations are sponsored in the data. If we believe that well-aligned sponsors are highly correlated with sponsored content

---

<sup>22</sup>From Table 7:  $9.18 - 1.2 - 7.44 = 0.54$

production, then the similar magnitudes of the structural parameter and the summary statistic somewhat reassure concerns about mismeasurement of the unobserved state.

The utility parameters from the second stage imply value functions and conditional choice probabilities derived from the nested logit assumption. Figure 4 shows the CCPs of the sponsored content choices, high and low disclosure. The left hand column is for the CCPs when  $\theta = \theta_L$ , the right is for states  $\theta = \theta_H$ . As expected, low disclosure is more common than high disclosure when  $\theta = \theta_L$ , but high disclosure is dominant when  $\theta = \theta_H$ . Sponsorship as a whole is much more frequent when there is a good brand match.  $\alpha_f > 0$  means that the cost of advertising to streamers decreases as the number of followers grows. This clearly can be seen in the CCP plots, as both high and low disclosure probabilities are upward sloping.  $r_f < 0$  implies that streamers value the outside option more as their following grows, but the increase in ACV offsets this effect as shown in Figures 4c and 4d; in both panels the probability of choosing no stream is decreasing with  $f$ . Lastly,  $\rho_{nest}$  being near zero suggests strong correlation between the utility shocks of high and low disclosure. This makes sense as they are the two sponsored content choices. As mentioned in Section 2, brands generally do not require streamers to disclose, so the monetary payoffs offered to the streamers for sponsored content should be similar irrespective of their disclosure decision.

In the data, about 1.8% of observations are sponsored streams. In simulations, the first stage parameters and the CCPs estimated above imply 2.22% of observations are sponsored streams. The reason for a slight over-estimation of sponsored streams is because of the transition parameters; in simulations, streamers grow faster in the model than in reality. As a result, the model implies that more streamers will enter into state spaces with higher probabilities of creating sponsored content. The model also does well in capturing the high and low disclosure distributions within sponsored streams. In the data, 14.2% of all sponsored streams have high disclosure. The model implies that 16.2% of sponsored streams are prominently disclosed; the slight overestimation again can be attributed to more streamers entering higher number of follower states.

## 7.2 Counterfactuals

### Removing the ability to obfuscate

For this counterfactual I remove the choice of low disclosure from a streamer’s choice set. This reflects the policy change of forcing high disclosure and removing avenues for obfuscation. An implementation of this policy could be some salient disclosure label, which platforms like Youtube have already implemented. Figure 5 plots the conditional choice probabilities of choosing sponsored streams in the current policy environment, as well as that in the counterfactual world where  $j = LD$  is removed from the choice set. The effect of the counterfactual policy on other organic and no stream is negligible at every state. Overall, I predict that the amount of sponsored content will drop to 1.86% of observations, down from 2.22%. Relatively, this means that the amount of sponsored content will decrease by 16.5 percent.

I break down the effect of the counterfactual policy by the brand alignment state. In Figure 5a, we see the biggest impact of the policy; the amount of sponsored content when the brand

Figure 4: Conditional Choice Probability Plots

Figure 5: Counterfactual 1: Removing Low Disclosure - Conditional Choice Probability Plots

alignment is low ( $\theta = \theta_L$ ), decreases at every state. In the low alignment state, sponsored content only occurs with a 1.69% frequency in the counterfactual, compared to 2.06% under status quo policies. Relatively speaking, this is a 18 percent decrease in the frequency of sponsored content. The counterfactual policy has almost no effect on sponsored content at high brand alignment states ( $\theta = \theta_H$ ); sponsored content occurs with at 16.2% frequency under the counterfactual, and at a 16.4% frequency in the status quo (see Figure 5b), a relative change of just 1.5 percent. Hence, almost all of the counterfactual policy’s effect is driven by streamers who reject poorly aligned sponsors they otherwise would have accepted in absence of the policy.

Ex-ante, it is unclear how a strict disclosure policy affects viewership on the platform. When low disclosure sponsored content is banned, some streamers substitute to the outside option of no stream and some substitute to organic content. The former should weakly decrease the amount of viewership on the platform, but the latter should improve viewership as better content attracts more viewers directly and also through the follower state transition. Without modeling followers’ demand and lacking information on followers’ outside option, I cannot make definitive statements about viewing behavior. By assuming that all viewers are homogenous so that ACV captures all viewership behavior (e.g. all viewers watch the same length of time), the change in total viewership on the platform after the policy is implemented is a positive 0.67%.

If one believes that sponsor alignment is positively correlated with vertical stream quality, then the results of this counterfactual refutes efficiency arguments for nondisclosure (Coase, 1979). By decreasing the number of poorly-aligned sponsors, we improve consumers’ experience on the platform because content quality gets better. This creates an interesting dilemma for the platform, as stricter disclosure policies may irritate influencers but give consumers fewer poorly aligned streams to navigate.

## Increasing match quality

Platforms may be concerned about their creators’ content being flooded with low quality sponsors. As a result, the platform may step in to help match creators with brands. In the payola context, this is akin to the radio stations working with record labels to help their DJs find sponsored music.

This is a practice that is becoming more popular among platforms; Twitch has a program called bounty board that offers a “bounty” for streamers if they choose one of the sponsored game options from a menu of potential sponsors. Twitch has an incentive to improve their ability to broker deals between sponsors and streamers. If done well, such a program will be a comparative advantage over other streaming platforms for retaining streamers. Twitch can also make more revenue from brokering such sponsored deals. On the consumer side, improving the match between streamer and sponsors may improve sponsored content quality, making it more palatable on average for viewers. If Twitch can improve its matching ability, then we would expect more sponsored content.

In this counterfactual, I quantify what happens if the rate of high brand alignment increases as a result of better matching. This can be through the platform side or through talent management

agencies who negotiate deals for influencers. Table 9 displays the counterfactual simulations when

$P(\theta = \theta_H)$	% HD Streams	% LD Streams	% Sponsored Streams
0.011 (status quo)	0.31	1.91	2.22
0.022	0.46	1.92	2.39
0.05	0.83	1.96	2.78
0.1	1.49	2.02	3.51
0.2	2.84	2.14	4.97

Table 9: Effect of better brand alignment on sponsorship frequency - 100 simulations

$P(\theta = \theta_H)$  takes on various values. When the probability doubles, the proportion of sponsored streams increases from 2.22% of observations to 2.39%, a eight percent relative increase. Notably, the frequency of low disclosure streams barely changes while the frequency of high disclosure streams increases by  $1.5\times$ . The frequency of sponsored streams doubles when the probability of a good brand match reaches 10-20%.

Overall, sponsorship frequency does not change too much with alignment. Even a well-aligned match rate of 20% leads to less than 5% of streams being sponsored, with high disclosure streams driving almost all of the change. This is expected given how brand alignment  $\theta$  affects high disclosure outcomes through more channels in the model. For platforms, this finding may suggest that improving alignment between sponsors and streamers may be worthwhile. Streamers would benefit from having a better selection of sponsors to work with, while refraining from creating too much sponsored content because of the tradeoffs involved.

## 8 Conclusion

This paper distinguishes mechanisms behind pay-for-placement and advertising in the digital economy to explain why voluntary disclosure occurs in online livestreaming influencer marketing. Disclosure is used as a lever to trigger advertising mechanisms when the influencer or brand wants to signal the sponsored nature of the content. A stylized example shows the differences between placement and advertising and provides justification for why non-disclosure in pay-for-placement settings may be efficient. Descriptive findings imply that influencer marketing is more similar to advertising, and the structural model finds that prominent disclosure enforcement leads to better outcomes for the platform and consumers.

My findings can be extended to more general settings where paid placement occurs. They support Coase (1979)’s rationale that non-disclosure in radio is efficient because the disclosure imposes great costs on the listener and the radio DJ. Regulators interested in other traditional placement settings, such as television, movies, or grocery stores, need to weigh the placement vs advertising mechanisms before implementing policy regarding disclosure. I challenge how the traditional marketing mix (4Ps) operate in the digital economy, displaying the importance of separating placement and promotion even when they operate similarly. My analyses can be conducted on other

platforms such as YouTube, Instagram, and Tiktok. Regulators and platforms should assess if influencer marketing contains advertising mechanisms that make disclosure policy efficient.

There exist a few caveats in my analysis. First, the way in which I deal with selection may not be completely satisfactory. Selection into prominent disclosure may come through more avenues than just brand alignment. Unfortunately, powerful, exogenous variation that shifts influencers' incentives to disclose are absent in my setting. Second, incorporating heterogeneity is difficult in a dynamic structural model. The dynamics are necessary, however, to capture short and long-term tradeoffs of creating and disclosing sponsored content. Third, competition may factor into the amount of engagement influencers receive. My paper is mostly agnostic to competition. In the livestreaming setting, competition can have both a market expansion effect and a market share stealing effect. Lastly, a richer viewership demand model in conjunction with price data on influencer payments can help pin down welfare effects for all relevant stakeholders. I hope to address these shortcomings either in later revisions of this paper or in future work.

Avenues for future work further dive into the differences between placement and promotion. For example, payola may have resulted in lower equilibrium wages for the DJ, as the radio station can afford to pay the DJ less when they are supplemented by payola. In essence, the existence of payola was a transfer from record labels to radio stations. This raises the question as to why Twitch does not extract these revenues from influencers and brands today. There are also pertinent questions related to market entry. Slotting fees redistribute risks from grocery stores to brands, making stores more willing to stock new and unique brands for consumers. Today, it is an outstanding question as to whether or not influencers decrease the costs of entry for brands. Conversely, one could also ask whether or not sponsors decrease influencers' barriers to becoming a "bigger" influencer by legitimizing their opinions. These are all exciting directions for future research.

## A Appendix

### A.1 Pooling equilibrium proof

*Proof:* I show that no type wants do deviation with a sufficiently large enough penalty for disclosure. Let  $Q = (\lambda - p_H)(\theta_H - \theta_0) + (1 - \lambda - p_L)(\theta_L - \theta_0)$ :

$$\begin{aligned}
c(HD|\theta) - c(LD|\theta) &> Q \\
&> (\lambda - p_H)(\theta_H - \theta_0) + (1 - \lambda - p_L)(\theta_L - \theta_0) \\
&> (\lambda - p_H)\theta_H + (1 - \lambda - p_L)\theta_L - (1 - p_L - p_H)\theta_0 \\
(1 - p_L - p_H)\theta_0 + p_L\theta_L + p_H\theta_H - c(LD|\theta) &> \lambda\theta_H + (1 - \lambda)\theta_L - c(HD|\theta) \\
\pi^*(LD|\theta) &> \pi^*(HD|\theta).
\end{aligned}$$

It is worth to note in many cases,  $\lambda \approx 0$  is a reasonable consumer behavior assumption. In these cases, if  $\theta_H \geq \theta_0$ , then as long as  $c(HD|\theta) \geq c(LD|\theta)$  the pooling equilibrium conditions are satisfied. As disclosure becomes more of a positive signal ( $\lambda \rightarrow 1$ ), the cost of high disclosure must increase to maintain a pooling equilibrium.

### A.2 Separating Equilibrium

*Proof:* To low and organic types from mimicking the high type, we need to ensure that reputation costs are high enough to deter.

Choose  $M > \theta_H - (1 - \lambda_L)\theta_0 - \lambda_L\theta_L$ :

$$\begin{aligned}
c(HD|\theta) - c(LD|\theta) &\geq M \\
&> \theta_H - (1 - \lambda_L)\theta_0 - \lambda_L\theta_L \\
(1 - \lambda_L)\theta_0 + \lambda_L\theta_L - c(LD|\theta) &\geq \theta_H - c(HD|\theta) \\
\pi^*(LD|\theta) &> \pi^*(HD|\theta).
\end{aligned}$$

We also need to check that  $\theta_H$  types will never pool with low and organic types. Choose  $N \leq \theta_H - (1 - \lambda_L)\theta_0 - \lambda_L\theta_L$ :

$$\begin{aligned}
c(HD|\theta_H) - c(LD|\theta_H) &\leq N \\
&\leq \theta_H - (1 - \lambda_L)\theta_0 - \lambda_L\theta_L \\
(1 - \lambda_L)\theta_0 + \lambda_L\theta_L - c(LD|\theta_H) &\leq \theta_H - c(HD|\theta_H) \\
\pi^*(LD|\theta_H) &\leq \pi^*(HD|\theta_H)
\end{aligned}$$

Recall  $Q$ :

$$Q = (\lambda - p_H)(\theta_H - \theta_0) + (1 - \lambda - p_L)(\theta_L - \theta_0)$$

In the separating equilibrium  $\lambda = 1$  and  $p_H = 0$ ,

$$Q = \theta_H - (1 - p_L)\theta_0 - p_L\theta_L$$

$N = Q$  if  $\lambda_L = p_L$ . If  $\lambda_L > p_L$ , then  $N < Q$ . If  $\lambda_L < p_L$ ,  $N > Q$ .

It is important to note that when  $\theta_H \geq \theta_0$ , there will always be a  $N$  or  $Q > 0$  that can satisfy the above condition. When  $\theta_0 > \theta_H$ , that may not exist, and therefore the separating equilibrium may not necessary exist. However, for  $\theta_0 > \theta_H$  such that  $\theta_H$  is sufficiently big enough and  $\lambda_L$  is sufficiently small enough, a separating equilibrium may still exist.
